Abstract

An environmentally friendly and inexpensive substitute to the widely used poly(vinyl alcohol) (PVA) has been developed from soy proteins for textile warp sizing. Textile processing is the major source of industrial water pollution across the world, and sizing and desizing operations account for nearly 30 % of the water consumed in a textile plant. PVA is one of the most common sizing agents used for synthetic fibers and their blends due to PVA's easy water solubility and ability to provide desired sizing performance. However, PVA does not degrade and is a major contributor to pollution in textile effluent treatment plants. Although considerable efforts have been made to replace PVA with biodegradable sizing materials, the performance properties provided by PVA on synthetic fibers and their blends have been unmatched so far. Soy proteins are inexpensive, biodegradable, and have been widely studied for potential use in food packaging, as resins and adhesives. In this research, the potential of using soy proteins as textile sizing agents to replace PVA was studied. Polyester and polyester/cotton rovings, yarns, and fabrics sized with soy protein showed a considerably better improvement in strength and abrasion resistance compared to commercially available PVA-based size. Soy protein size had a 5-day biochemical oxygen demand / chemical oxygen demand ratio of 0.57 compared to 0.01 for PVA indicating that soy protein sizes were easily biodegradable in activated sludge. The total and ammo-

nia nitrogen released from the proteins also did not adversely impact the biodegradability. Good sizing performance and easy biodegradability demonstrate that soy protein-based sizes have potential to replace PVA-based sizes leading to substantial benefits to the textile industry and the environment.

Keywords: sizing, poly(vinyl alcohol), biodegradation, proteins, ammonia, cohesion

Introduction

Textile production consumes considerable amounts of water and chemicals and the textile industry is a major contributor to water pollution and toxic discharges across the world. Producing a kilogram of fabric is estimated to consume about 600–1,000 kilogram of water during the preparation, dyeing, and finishing stages depending on the type of fabric made and processes used. A significant proportion of the dyes and chemicals used for textiles which are released into effluents are reportedly hazardous to the environment (Bisschops and Spanjers 2003). Among the various textile manufacturing stages, sizing is a critical process of imparting additional protection to warp yarns to withstand the abrasive forces during weaving. The protection to yarns is imparted by coating the yarns with chemicals called sizing agents/size. Starch and starch derivatives, car-

boxymethyl cellulose, and synthetic polymers such as poly(vinyl alcohol) (PVA) have traditionally been the most widely used sizing chemicals (Cacho 1980; Cai et al. 2003; Du et al. 2007). In addition to the primary ingredient, sizing chemicals contain many other additives such as waxes and lubricants, softeners, emulsifiers, and finishing and wetting agents. Starch and starch derivatives are mainly used for cotton and cotton blends and PVA is mainly used for synthetic fibers and their blends. A size is evaluated based on its performance during weaving, ability to be removed (desized) after weaving, cost of the chemical, and biodegradability. A good size should decrease the yarn breakage during weaving, prevent or decrease hairiness, reduce electrostatic problems, and be easily removed during desizing (Cai et al. 2003). Although starch and starch derivatives meet most of these requirements for cotton yarns, starch sizes do not provide good performance during weaving for synthetic fibers and their blends and are sometimes difficult to be desized when used on tightly woven fabrics. PVA is a preferred sizing agent for synthetic fibers and their blends due to its excellent properties such as film strength, flexibility and adhesiveness, and water solubility, which makes it easier to be desized.

Although sizing is an inevitable process and offers substantial benefits during weaving, there are several problems associated with sizing. Sizing and desizing contribute significantly to the effluents generated in a textile plant and are reported to be responsible for about 50–80 % of the chemical oxygen demand (COD) in textile waste water (Gartiser et al. 1998). Starch-based sizes are reported to have a COD and biochemical oxygen demand (BOD) in the range of 900–1,200 and 500–600 mg O₂/g, whereas PVA has a COD of 1,700 mg O₂/g and a BOD of 30–80 mg O₂/g. Similarly, polyacrylates have a COD of 1,350–1,650 mg O₂/g but low BOD of 50 mg O₂/g. It is estimated that 1 g of PVA generates 0.016 g 5-day BOD (BOD₅) or 1.6 g COD which means a low BOD₅ to COD ratio indicating the poor degradability of PVA (Goswami et al. 2004; Lin and Lan 1993). It is reported that only about 60 % of PVA was degraded after 4 months of incubation under anaerobic conditions and 0–12 % of PVA was degraded in anaerobic sludge after 77 days (Liu et al. 2010). The low BOD of the synthetic sizes is a concern, and efforts have been made to replace the synthetic sizes with biodegradable sizes (Matos et al. 2011).

Chemical and physical modification of starch is the most common approach used to develop biodegradable sizes for synthetic fibers and their blends (Mohamed et al. 2010). Efforts have also been made to recover PVA and avoid release into the effluent and also to develop methods to increase the degradation of PVA (Moreau 1981; Moreland 1980). Special microorganisms, combination of chemical and biological treatments, and modification to anaerobic reactors have been done to improve

the biodegradability of PVA (Narayana 1993; Opwis et al. 1999; Ramesh Babu et al. 2007). Attempts have also been made to eliminate the need for sizing (Ramesh Babu et al. 2007). Unfortunately, most of these attempts have been unsuccessful, and currently, there are no sizing agents that can provide the desired sizing properties, biodegradability, and cost-effective substitute to PVA for sizing synthetic fibers and their blends.

One of the major criteria in evaluating a sizing chemical is the ability to form film and have good adhesion to the substrate. Plant proteins such as soy proteins, wheat gluten, and zein have been extensively studied as films for food packing and other applications. Plant proteins have been made into fibers and nano- and microparticles and have also been used as matrix for composites (Reddy and Yang 2011a, b; Rongrong et al. 2011; Xu et al. 2011). Plant proteins are also available in large quantities at low cost and are easily biodegradable. These properties make plant proteins ideal candidates as sizing chemicals. However, there are no reports on using plant proteins for sizing. In this research, we have used soy proteins to size polyester and polyester/cotton rovings, yarns, and fabrics. The effect of sizing conditions on the properties of the sized materials and the biodegradability of the soy protein size has been studied in comparison to commercially available PVA-based sizes.

Experimental

Materials

Soy proteins (PRO-FAM 646) were provided by ADM International, Decatur, IL, USA. The polyester/cotton (65/35) rovings (70s Hank) and yarns (15 Ne) used in the study were supplied by Mount Vernon Mills. The polyester (Nan Ya, Lake City, SC) used in the blend was of 1.4 denier, 1.5-in. cut length with breaking tenacity of 6.5 g/denier and elongation of 27.8 %. The cotton used in the polyester/cotton blend was Southeastern cotton (strict low middling) with an average length of 27 mm and a micronaire of 5. The 100 % polyester rovings and yarns were supplied by Shuford Yarns LLC, Hickory, NC, USA. The fabrics used (polyester/cotton (P/C) type 7435 and 100 % polyester type Dacron 54) were purchased from Testfabrics Inc., West Pittston, PA, USA. PVA-based commercially available sizes supplied by major sizing chemical manufacturers in the USA were used to compare the sizing performance of the proteins. All other chemicals used were purchased from VWR International.

Sizing

Soy proteins (0.25 to 2 %) were pretreated in alkaline solutions at a preset temperature for a predetermined

time. The pretreatment conditions such as concentration of alkali (0.01 to 0.1 %), time, and temperature (20–90 °C) were varied to study the effect of soy protein pretreatment conditions on sizing performance and to identify the optimum conditions for preparing the size. After the pretreatment, the protein solution was adjusted to the desired pH (7–10). Samples (rovings, yarns, or fabrics) were treated (immersed) in the sizing solution at 90 °C for 5 min. The rovings and yarns were wound onto a frame to have adequate tension and immersed in the sizing solution. In the case of fabrics, the sizing solution was padded onto the fabrics ensuring that a constant pickup was obtained. The commercial PVA sizes were applied on to the rovings, yarns, and fabrics using the manufacturer-recommended conditions. After sizing, the materials were conditioned at 21 °C and 65 % relative humidity for about 24 h before testing. The amount of size (percent size add-on) on the rovings, yarns, and fabrics was determined by weighting oven-dried (105 °C) samples before and after sizing.

Characterization

Viscosity

Viscosity of the sizing solution was measured in a rheometer (Brookfield, model R/S Plus) using different concentrations and temperatures of sizing solutions. A CC-48 cup and about 70 g of solution was used for each test. The spindle and cup were immersed in a water bath to ensure that a constant temperature was maintained throughout the study. Viscosity was recorded in terms of millipascal-second.

Tensile properties

The sized rovings were tested to determine their tensile strength and elongation as an indication of cohesiveness of the soy proteins to the fibers in the rovings. Testing was performed on a MTS tensile tester (model: QTest 10) using a gauge length of 10 cm and a crosshead speed of 50 mm/min. Yarns were tested on an Instron tensile tester (model 5555) using a gauge length of 10 cm and a crosshead speed of 18 mm/min. At least 20 tests were conducted for each sizing condition, and each experimental condition was repeated at least three times.

Abrasion resistance

Abrasion resistance was determined on both yarns and fabrics. Yarn abrasion tests were conducted on a cohesion tester (model Y 731D; Changzhou Huafang Textile Instrument Co., Ltd., Changzhou, China). In this tester, yarns were wrapped around pins to create adequate tension and rubbed on top to simulate the frictional forces experienced during weaving. The number

of cycles required to break the yarns was recorded. The higher the number of cycles required to break the yarns, the higher was the resistance to abrasion. Fabrics were tested for the changes in abrasion resistance on a Universal Wear Tester using “0” grade emery paper and 1-lb weight for the polyester fabrics and 0.5-lb weight for the P/C fabrics. The number of cycles required to create a hole in the fabric was used as an indication of the abrasion resistance.

Desizing

The sized fabrics with a known amount of percent add-on were desized to determine the efficiency of removal of the soy proteins and PVA from the fabrics. Desizing was performed by treating the sized fabrics in various ratios of water to fabric at different temperatures and for different times. After treatment, the fabrics were rinsed in cold/warm water and then dried. The fabrics were weighed before and after desizing and the loss in weight was calculated to determine the desizing efficiency.

Biodegradation

COD and BOD

Biodegradation of the sizing solutions was determined in terms of COD, BOD₅, and changes in total nitrogen and ammonia nitrogen. To determine the biodegradation of the sizing solutions, waste water sludge from the local waste water treatment plant was used. The sludge was first diluted and then aerated in the laboratory for 2 days to acclimatize the microorganisms. The sizing solutions were added into the sludge at a concentration of 300 ppm. Based on the normal percent add-on after sizing and the amount of water consumed for sizing, desizing, and other finishing operations, the typical concentrations on size in a textile waste water treatment plant will be about 100–150 ppm. A higher concentration (300 ppm) was deliberately chosen to understand the effect of proteins on biodegradability. Protein samples were aerated with the sludge for up to 6 days. At the desired treatment time, the sludge solution was collected and centrifuged to remove the solids. The top liquid layer was collected to analyze for the COD, BOD₅, and total and ammonia nitrogen. COD tests were conducted according to the United States Environmental Protection Agency method 8000. A high-range (20–1,500 mg/L) COD test kit (TNT 822) was purchased from Hach Company and used for the study.

The 5-day BOD test was performed according to the Standard Methods for the Examination of Water and Waste Water published by the American Public Health Association. The oxygen levels in the water with and without sludge and before and after treatment were measured using a dissolved oxygen probe (Hach Company,

HQ 440D multi). Samples were appropriately seeded and the water used for the test conformed to the standard and had an oxygen depletion of less than 0.2 mg/L in 5 days.

Total and ammonia nitrogen

The total nitrogen in the sludge was calculated based on the alkaline persulfate oxidation digestion method and ammonia nitrogen was calculated using salicylate and hypochlorite in an alkaline phosphate buffer. The buffer turns the effluent water into green color and the intensity of the color being proportional to the amount of ammonia in the sample. To determine the ammonia nitrogen, the sample was added with salicylic acid (50 g/L), potassium sodium tartrate (50 g/L), sodium nitroferrocyanide (10 g/L), and sodium hypochlorite solution (3.5 g/L active chlorine). The mixture was allowed to stand for 1 h at room temperature. The samples were later measured with a spectrophotometer (Beckman Coulter: model DU 720) for absorbance at 697 nm using a cuvette. A calibration curve prepared with known concentrations of ammonia was used to determine the ammonia in the samples.

Total nitrogen was determined by adding potassium persulfate into the sample and digesting the mixture at 120 °C for 40 min. After digestion, 1 mL HCl was added to terminate the digestion. The total nitrogen was determined by measuring the absorbance at 220 and 275 nm for the blank (distilled water) and the sample with size, respectively. The concentration of total nitrogen was calculated using calibration curves that had $R^2 > 0.999$.

Film preparation and properties

Films were prepared from soy proteins and PVA for comparison. Soy proteins (6 %) were heated in pH 12 water at 90 °C for 30 min. After heating, the solution was cast on Teflon-coated glass plates and allowed to dry at 21 °C and 65 % relative humidity. Films were conditioned for 35–40 h and collected. To prepare PVA films, 6 % PVA was heated in water to 90 °C and held for 30 min. PVA solution was also cast on glass plates and the films formed were collected after evaporating water and conditioning under standard conditions. Tensile properties of the films were tested according to ASTM D822 with an MTS (QTest 10) tensile tester using a gauge length of 2 in. and a traverse speed of 10 mm/min. At least 20 samples obtained from two to three films cast separately were tested and the average and standard deviation are reported.

Statistical analysis

Data generated were analyzed by Tukey's multiple pairwise comparisons using SAS software (SAS institute Inc., Cary, NC, USA). Statistical significance was considered if the p value was < 0.05 .

Results and discussion

Effect of size pretreatment conditions on tensile properties

The effect of increasing alkali concentration from 0.01 to 0.1 % on the tensile strength and elongation of polyester and polyester/cotton rovings is shown in Figure 1. Strength of the P/C and polyester roving was significantly higher when a low concentration (0.01 and 0.03 %) of alkali was used. At the highest alkali concentration (0.1 %), the strength was considerably lower for both the polyester (38 % lower) and P/C (39 % lower) rovings compared to their respective strength at 0.01 % alkali, but there was no significant decrease in the strength or elongation when the alkali concentration was 0.05 or 0.08 %. The P/C rovings had higher strength but lower elongation than the polyester roving due to the large size (diameter) of the P/C roving and inherent property differences between cotton and polyester, especially elongation. Pretreating the soy proteins at high alkali concentrations hydrolyzed the proteins and therefore decreased the tensile strength with an increasing concentration of alkali. Treating with different concentrations of alkali also changed the viscosity which affects the size penetration and therefore the performance properties (Saravanan et al. 2009). Soy proteins (1 %) had lower viscosity 1.5 mPa s compared to 2.0 mPa s for PVA that would enable better penetration of soy protein into the roving. The viscosity of the soy protein solutions developed in this research is within the range reported for commonly used sizing agents (Cacho 1980).

Varying the pretreatment time between 20 and 40 min did not show any major effect on the strength or elongation as seen in Figure 2, except for the P/C rovings which had a slightly lower (11 %) strength when pretreated for 40 min. Although longer pretreatment time will hydrolyze the proteins resulting in lower strength and elongation, the range of pretreatment times studied in the research were considerably narrow, and therefore, there was no significant change in the tensile properties with an increasing pretreatment time.

A study of sizing at room temperature (20 °C) and at 90 °C showed considerable changes in terms of strength and elongation of the roving as seen in Figure 3. Strength of polyester and P/C roving and elongation of the polyester roving were much higher when sized at 90 °C compared to sizing at 20 °C, whereas no change was observed in the elongation of the P/C roving when sized at the two temperatures. Higher temperatures enable the protein size to penetrate into the fibers and bind the fibers together leading to higher strength and elongation. Attempts are being made to reduce energy consumption in textile mills by sizing at room temperature instead of the traditional high-temperature (85–95 °C) sizing (Sawhney et al. 2005). The performance of cold-sized yarn was reported to be similar to that of yarns

Figure 1. Influence of concentration of sodium hydroxide used during pretreatment of soy protein on the tensile properties of polyester and P/C roving at similar percent add-on (5 %). Soy protein (1 %) was pretreated at 90 °C for 30 min. For each property, data point with different letters indicates statistically significant difference.

sized at high temperatures. Although the properties of the rovings sized at 20 °C were lower than those sized at 90 °C, the strength improvement provided by the soy protein size after sizing at 20 °C is probably adequate to protect the yarns during weaving.

Changing the pH of the sizing solution from 7 to 10 affected the tensile strength of the P/C roving but did not show any major influence on the polyester rovings as seen in Figure 4. At pH 7, the peak load of the P/C roving was about 112 N compared to 150 N at pH 8. A slight increase in elongation was observed at pH 9 for polyester and at pH 8 for P/C roving. Considerable de-

crease in strength of the P/C roving was observed when sizing was done at pH values 9 and 10. Variations in the strength of the roving at different pH values should mainly be due to the differences in attraction/repulsion between the proteins and fibers at the different pH values. Overall, the optimum sizing conditions obtained in this research are typical sizing conditions used in the textile industry. The ability of the soy proteins to provide a good improvement in strength and elongation to the rovings under a range of size preparation conditions indicates that soy proteins could be used for sizing under varying conditions at textile plants.

Figure 2. Influence of pretreatment time on the tensile properties of polyester and P/C roving treated with 1 % soy protein at 90 °C and pH 8 with a percent add-on of about 5 %. Statistical differences in pretreatment time, if any, for each property is indicated with different letters.

Figure 3. Effect of sizing temperature on the tensile properties of polyester and P/C roving sized with soy proteins and having 5 % add-on. The size was pretreated at 90 °C for 30 min. For each property, data point with different letters indicates statistically significant difference

Effect of percent add-on on sizing performance

The performance of a size is directly related to the amount of size added onto the materials. Generally, increasing the amount of size up to an optimum level should increase the performance properties. As seen in Figure 5, increasing the concentration of soy protein size continually increased the strength of both the polyester and P/C rovings. Rovings sized with PVA also showed a continual increase in strength with increasing percent add-on but the percent change was considerably lower. At the lowest percent add-on of about 2 %, the P/C and polyester rovings sized with soy proteins had strength of 108 and 83 N, respectively, compared to 168 N for PVA. Further increase in percent add-on did not show

a major improvement in strength for the rovings sized with PVA but the strength of the roving sized with soy proteins increased. At about 12 % add-on, the polyester and P/C roving sized with soy proteins had strength of 196 and 231 N, respectively, very similar to the strength of the rovings sized by PVA. However, a much higher percent add-on (12–13 %) was necessary for the soy protein size to provide strength comparable to PVA (6–7 % add-on).

It should be noted that in addition to the primary ingredient PVA, size contains several additives such as plasticizers, emulsifying agents, and others that will improve the adhesion and performance properties of the sized materials. The addition of such additives could also make the soy proteins provide better performance

Figure 4. Effect of sizing pH on the tensile properties of polyester and P/C roving treated with 1 % soy protein that was pretreated at 90 °C for 30 min. For each property, data point with different letters indicates statistically significant difference.

Figure 5. Influence of percent size add-on on the tensile properties of polyester and P/C roving treated with 1 % soy protein that was pretreated for 30 min at 90 °C. PVA and soy protein sizing was done at 90 °C for 5 min. On each curve, data points with different letters, numbers, or symbols indicate statistically significant difference.

at lower percent add-on. Also, PVA films had much higher breaking stress (24.3 ± 3.9 MPa) and elongation (278 ± 34 %) compared to 1.6 ± 0.2 MPa and 1.9 ± 0.3 % for soy proteins, which also contributes to the higher strength of the rovings treated with PVA. The ability of soy proteins to provide similar performance to PVA despite the films having relatively low strength and elongation should mainly be due to the better affinity between the proteins and the fibers.

Performance of sized materials at different relative humidities

During weaving, the humidity of a weaving room varies between 55 and 80 % and it is important that the size provides adequate protection to the yarns at different humidities. As seen in Figure 6a, the peak load of both

the polyester and P/C rovings is significantly lower at 55 % humidity compared to their respective properties at 65 and 75 % humidity. At low humidity, the protein film on the rovings is probably less flexible, and therefore, we see a decrease in strength and elongation. Also, the higher moisture at high humidities acts as lubrication and improves the strength and elongation. However, most modern weaving rooms operate at 65–70 % humidity at which the soy protein sizes show good performance. The effect of humidity was more pronounced on P/C because cotton absorbs more moisture than polyester at higher humidities. Both the polyester and P/C rovings sized with PVA were relatively unaffected by humidity as seen in Figure 6b. A slight increase in strength for the P/C rovings and elongation of the polyester rovings was observed at 65 and 75 % humidity compare to the properties at 55 % humidity. As with

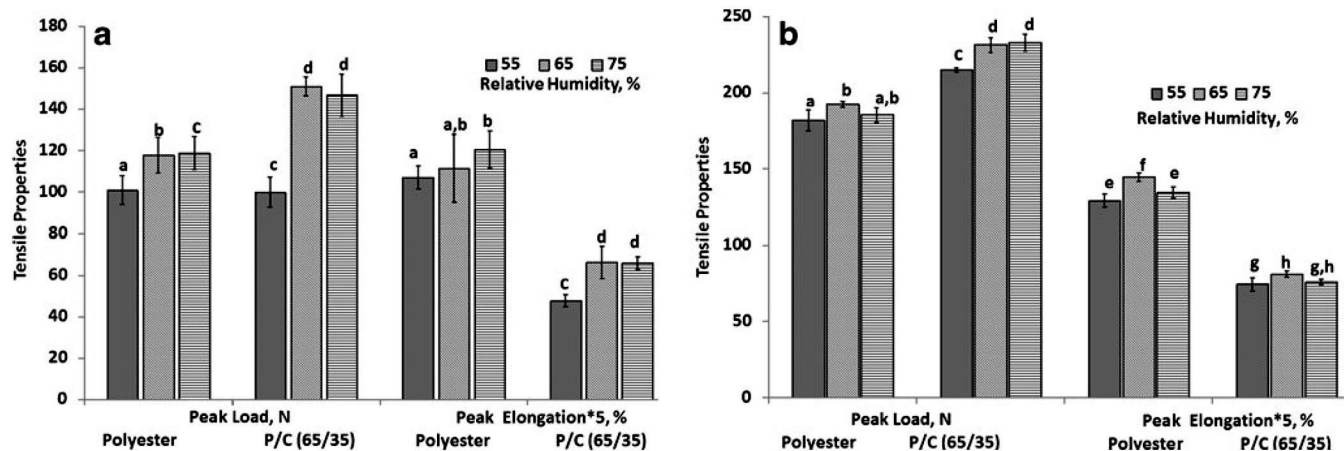

Figure 6. Influence of percent relative humidity on the tensile properties of polyester and P/C rovings treated with 1 % soy protein that was pretreated for 30 min at 90 °C (a) compared to the changes in tensile properties for rovings treated with PVA (b). Soy protein sizing was done at 90 °C for 5 min. For each property, data point with the different letters indicates statistically significant difference

Figure 7. Changes in the breaking tenacity of P/C and polyester yarns sized with soy proteins and PVA at different percent add-on.

the proteins, lower humidity (55 %) should decrease the moisture on PVA, make the film brittle, and therefore decrease the strength and elongation.

Tensile properties of sized yarns

Sized yarns are expected to show an increase in tensile strength between 15 and 25 % depending on the count and type of yarns (Schonberger et al. 1997). Figure 7 shows that there was a marginal increase (5–12 %) in strength of the yarns after sizing with soy proteins and PVA. P/C yarns sized with soy protein showed a higher increase in strength than the yarns sized with PVA at low percent add-on. Increasing the percent add-on on P/C yarns increased the strength up to about 8 % add-on and the strength increase stabilized at higher percent add-ons. For polyester yarns, the strength increased continually with increasing percent add-on and the soy protein- and PVA-sized yarns showed a similar strength improvement at the different percent add-ons studied.

Abrasion resistance

Providing adequate protection to the yarns against the abrasive weaving actions is one of the most important properties of a sizing material. The resistance to abrasion was evaluated using both yarns and fabrics. After yarn abrasion tests, polyester yarns sized with soy proteins had considerably lower abrasion resistance (46 cycles) compared to 84 cycles for PVA. P/C yarns sized with soy protein showed slightly lower (62 cycles) compared to PVA (77 cycles). This result was different than the roving study where both the P/C and polyester roving showed a similar or better improvement in tensile prop-

erties compared to the rovings sized with PVA. However, the sized yarns, especially P/C yarns, had considerably higher abrasion resistance than the unsized yarns demonstrating the protective nature of the size.

Fabric abrasion showed (Figure 8) the higher resistance of the soy protein-sized materials for polyester, whereas P/C fabrics sized with soy proteins had considerably lower abrasion resistance than PVA at all percent add-ons studied. At 3 % add-on, polyester fabrics sized with soy proteins had a much higher abrasion resistance of 272 cycles compared to 186 cycles for fabrics sized with PVA. For P/C fabrics, the PVA size provided higher abrasion resistance (126 cycles) compared to soy proteins (89 cycles). This result is contrary to the roving strength increase where the P/C rovings showed a much higher improvement in strength than the polyester rovings sized with soy proteins. Roving strength increase is predominantly influenced by cohesion between fibers, whereas abrasion resistance is mostly related to the surface film on the fabrics. Soy proteins would have better cohesion for cotton than polyester, and therefore, the P/C roving had a higher strength increase than polyester rovings. Repulsion between the hydrophobic polyester and hydrophilic soy proteins probably results in the formation of a denser film on the surface of the polyester fabrics leading to better abrasion resistance of polyester fabrics compared to P/C fabrics.

Desizing

In addition to protecting the warp yarns during weaving, a good sizing material should also be easily removed (desized) from the fabrics. Although PVA is water soluble, desizing PVA requires high temperatures

Figure 8. Comparison of the abrasion resistance of polyester and P/C fabrics treated with soy protein and PVA at different percent add-on. On each curve, data point with the different letters indicates statistically significant difference.

and is normally done at 90 °C (Sun et al. 2012). As seen in Table 1, desizing even at mild conditions using low water to fabric ratio removes >95 % of the soy protein size on both the polyester and polyester/cotton fabrics. About 98 % of the size was removed when P/C fabrics were washed with 1:10 ratio of fabric to water at 20 °C and rinsed once. Under the same conditions, polyester fabrics had lower size removal of 78 %. Polyester fabrics were considerably thicker than the P/C fabrics, and therefore, there was less size removal even though soy proteins should have lower affinity to polyester compared to P/C. Additional rinsing after desizing at 20 °C could lead to higher percent size removal. Desizing accounts for a major portion (up to 50 %) of the water effluent in a textile plant and also requires enzymes and other chemicals (Vassallo 2005). The ability to remove the soy protein sizes using low amounts of water even at low temperatures and without any chemicals would mean considerable savings in energy consumption and less water as effluent in textile mills. Higher temperature and fewer rinses or lower temperature but addi-

tional rinses could be chosen to obtain the desired level of size removal.

Biodegradation

Chemical oxygen demand

Figures 9 and 10 depict the biodegradability of the soy protein size compared to PVA-based commercial size from 0 to 7 days of treatment in activated sludge. The soy protein size performed exceptionally well compared to PVA in terms of COD, BOD₅, and nitrogen as seen in Figs. 9 and 10. At 300 ppm, the PVA and soy protein sizes have similar COD values of 542 and 470 mg/L, respectively. However, treating the size solution in activated sludge showed a considerable degradation for soy protein but the COD of the PVA containing sludge did not change appreciably. After 2 days of treatment, the COD of the soy protein-containing sludge decreased to 82 mg/L from the initial value of 470 mg/L. The PVA-containing sludge did not show any significant decrease in COD.

Table 1. Comparison of the desizeability (percent size removed) for soy protein- and PVA-treated polyester and P/C fabrics at various desizing conditions

Type of fabrics	Desizing conditions					% Size removed	
	Temp, °C	Time, min	Water to fabric ratio		Rinsing times	Soy protein	PVA
			Washing	Rinsing			
Polyester	90	5	5:1	5:1	1	94.8 ± 2.6	76.7 ± 4.6
			5:1	5:1	2	98.6 ± 2.4	95.7 ± 3.8
			10:1	5:1	1	100	99.4 ± 1.0
	20	5	10:1	5:1	1	78.2 ± 2.1	61.5 ± 3.4
P/C	90	5	5:1	5:1	1	95.7 ± 4.0	77.0 ± 4.3
			5:1	5:1	2	98.3 ± 3.0	100
			10:1	5:1	1	100	100
	20	5	10:1	5:1	1	98.3 ± 1.8	82.3 ± 3.9
			10:1	5:1	1	98.3 ± 1.8	82.3 ± 3.9

Figure 9. Biodegradation of soy proteins and PVA (300 ppm) in activated sludge in terms of decrease in COD and BOD₅.

Five-day biochemical oxygen demand

The BOD₅ for the PVA and soy protein solutions without treating in activated sludge was 19.3 and 14.9 mg/L, respectively. After 3 days of treatment, the BOD₅ for the soy proteins decreased to 15 mg/L whereas the BOD₅ for the PVA-containing sludge did not show any appreciable change. The considerable decrease in COD and BOD for the soy protein size after just 3 days of treatment in the activated sludge indicated that the soy proteins could degrade easily in effluent treatment plants. The ratio of BOD₅/COD for soy proteins was 0.57 compared to 0.01 at 0 day of treatment suggesting that soy protein contained considerably higher organic material and could be easily degraded in effluent treatment plants (Zhu et al. 2012).

Total and ammonia nitrogen

The potentially higher amounts of nitrogen that could be released from proteins compared to PVA could be a concern for textile waste water treatment plants. Figure 10 showed that the total nitrogen released from soy proteins was initially 60 mg/L and continually decreased after treatment in activated sludge. A sharp decrease in total nitrogen and a corresponding increase in ammonia nitrogen were seen after 2 days of treatment indicating substantial degradation of soy proteins. The ammonia nitrogen release sharply decreased at 3 days because most of the soy proteins had already degraded at 2 days and there was negligible ammonia release after 3 days. The low levels of total and ammonia nitrogen released from soy proteins after 3 days of treatment in activated sludge

Figure 10. Degradation of the soy proteins in activated sludge in terms of changes in total and ammonia nitrogen.

indicated that soy proteins will not adversely impact the operation of the effluent treatment plants.

Conclusions

Soy protein as a textile sizing agent provided polyester and P/C rovings, yarns, and fabrics improved or comparable properties to PVA-based size. Higher (12–13 %) add-on was required for soy protein size to obtain a roving strength improvement comparable to PVA (6–7 % add-on). Better interaction between soy proteins and cotton compared to polyester provided higher cohesion and therefore higher strength for the P/C rovings compared to the strength improvement on polyester rovings. However, soy proteins provided better abrasion resistance on polyester than P/C yarns and fabrics. Soy protein-treated fabrics were easily desized (>98 % removal) even with low amounts of water. Unlike PVA, soy proteins were easily biodegradable in activated sludge and the nitrogen in the proteins did not adversely impact the biodegradability. Performance of sized materials, relatively easy biodegradability, and simplicity in preparing the soy protein size are some of the advantages that promote the replacement of PVA with soy proteins for textile warp sizing. Adding sizing ingredients such as plasticizers or chemical modifications to the soy proteins may be necessary to obtain good sizing performance at lower percent add-on for the soy protein-sized materials.

Acknowledgments — Financial support for this work was partially from the Agricultural Research Division at the University of Nebraska-Lincoln, USDA Hatch Act, Multi-State Project S1054 (NEB 37-037) and Chinese National High Technology Research and Development Program 863 Project (2013AA06A307), the Fundamental Research Funds for the Central Universities (Item No. 2011D10543), the Doctoral Dissertation Innovation Program BC201040 of Donghua University, and the China Scholarship Council. We thank Jorge Samayoa and Brad Barber with the Lincoln Waste Water Treatment Facility for their help in the activated sludge studies.
